Abstract

We consider the problem of computing the monic gcd of two polynomials over an algebraic number field \( L = \mathbb{Q}(\alpha_1, \ldots, \alpha_n) \). Encarnacion, Langemyr and McCallum have already shown how Brown’s modular GCD algorithm for polynomials over \( \mathbb{Q} \) can be modified to work for \( \mathbb{Q}(\alpha) \).

Our first contribution is an extension of Encarnacion’s modular GCD algorithm to the case \( n > 1 \) without converting to a single field extension. Our second contribution is a proof that it is not necessary to test if \( p \) divides the discriminant. This simplifies the algorithm; it is correct without this test.

Our third contribution is the design of a data structure for representing multivariate polynomials over number fields with multiple field extensions. We have a complete implementation of the modular GCD algorithm using it. We provide details of some practical improvements.

Our fourth contribution is a generalization of the reduced discriminant to the case \( n > 1 \). Although not used by our algorithm, it is useful for other algorithms, for example for the computation of the algebraic integers.

1 Introduction

We recall the relevant details of the so called modular GCD algorithm first developed by Brown in [3] for polynomials over \(\mathbb{Z}\) and then by Langemyr and McCallum in [6] and Encarnacion in [4] for polynomials over \(L = \mathbb{Q}(\alpha)\), which we shall generalize to \(L = \mathbb{Q}(\alpha_1, \ldots, \alpha_n)\). First let us fix some notation.

We denote the input polynomials by \(f_1\) and \(f_2\), their monic by \(g\). The cofactors are the polynomials \(f_1/g\) and \(f_2/g\).

If \(f \in \mathbb{Q}[x]\) then let the denominator \(\text{den}(f)\) be the smallest positive integer such that \(\text{den}(f)f \in \mathbb{Z}[x]\). See section 2 for the definition of \(\text{den}(f)\) if \(f \in \mathbb{Q}[\alpha_1, \ldots, \alpha_n][x]\). The associate \(\tilde{f}\) of \(f\) is defined as \(\tilde{f} = \text{den}(g)g\) where \(g = \text{monic}(f)\). Here monic\((f)\) is defined as \(\text{lcm}(f)^{-1}f\) where \(\text{lcm}(f)\) is the leading coefficient of \(f\). Define the semi-associate \(\tilde{f}\) as \(rf\) where \(r\) is the smallest positive rational number for which \(\text{den}(rf) = 1\).

Computing the associate \(\tilde{f}\) is useful for removing denominators, but could be expensive if \(\text{lcm}(f)\) is a complicated algebraic number. So we preprocess the input polynomials in our algorithm by taking the semi-associate instead. If \(\text{lcm}(f) \in \mathbb{Q}\) then the two notions are the same up to a sign:

\[
\tilde{f} = \pm \tilde{f} \iff \text{lcm}(f) \in \mathbb{Q}
\]

**Examples:** If \(f = 2x - 2/3\) then \(\tilde{f} = \tilde{f} = 3x - 1\). If \(\alpha = \sqrt{2}\) and \(f = -\alpha x + 1\) then \(\tilde{f} = f\), monic\((f) = x - \alpha/2\) and \(\tilde{f} = 2x - \alpha\).

The modular GCD algorithm computes the monic gcd \(g \in L[x]\) of \(f_1\) and \(f_2\). It does this by reducing \(f_1, f_2\) modulo one or more primes and calling the Euclidean algorithm \(\mod p\) for each of these primes \(p\). If \(p\) is a good prime, the Euclidean algorithm \(\mod p\) returns \(g \mod p\). To reconstruct \(g\) from these modular images, one can either try to construct a integer-multiple of \(\tilde{g}\) or one can use rational reconstruction (see Wang [9]) to construct \(g\) directly. If the former approach is used, one needs to know in advance some positive integer \(\gamma\) that is divisible by \(\text{den}(g)\). If one follows this approach then an important difficulty is to determine a good value for \(\gamma\). For \(n = 0\) one may take \(\gamma\) to be the gcd of the integers \(\text{lcm}(\tilde{f}_1), \text{lcm}(\tilde{f}_2)\). But a priori bounds for \(\gamma\) are often too pessimistic, especially when \(n > 0\) when it includes a bound for the defect. As in Encarnacion’s algorithm we will use rational reconstruction since it is generally superior because it avoids this problem. See section 1.5 for other advantages of this approach. The following definition illustrates the various problems of the modular GCD algorithm.
Definition 1 Let $f_1, f_2 \in L[x]$ and $g$ be their monic gcd. We will distinguish four types of primes.

- lc-bad primes. Let $m_1, \ldots, m_n$ be the minimal polynomials of the field extensions $\alpha_1, \ldots, \alpha_n$. If any leading coefficient of $f_2, m_1, \ldots, m_n$ vanishes mod $p$ then we call $p$ an lc-bad prime.

- Fail primes. If $p$ is not an lc-bad prime, and the Euclidean algorithm mod $p$ returns “failed”, then $p$ is called a fail prime.

- Unlucky primes. If $p$ is not an lc-bad prime nor a fail prime, and if the output of the Euclidean algorithm mod $p$ has higher degree than $g$, then $p$ is called an unlucky prime.

- Good primes. A prime $p$ is called a good prime if the Euclidean algorithm mod $p$ returns $g$ mod $p$. Theorem 1 in section 2 says that all primes that are not lc-bad are either fail, unlucky or good.

Remarks:

1. Our definition of lc-bad prime is not symmetric in $f_1, f_2$. It could be that $p$ is lc-bad for $f_1, f_2$ but not lc-bad for $f_2, f_1$. In that case, because of how we set up the algorithm, we should either: not use $p$, or: interchange $f_1, f_2$ mod $p$ before calling the Euclidean algorithm mod $p$.

2. Our definitions are not the same as the standard definitions in [3]. For example, it is possible that the Euclidean algorithm mod $p$ fails even if the monic gcd of $f_1$ mod $p$, $f_2$ mod $p$ exists and equals $g$ mod $p$. We call such $p$ a fail prime and not a good prime. This distinction is not necessary if $f_1, f_2 \in \mathbb{Q}[x]$ where there are no fail primes.

3. If $p \mid \text{den}(g)$ (in the standard definition these primes are called bad primes) then $g$ mod $p$ is not defined and so $p$ can not be a good prime. According to theorem 1, $p$ must then be either lc-bad, fail, or unlucky.

4. Minimal polynomials are monic so the leading coefficients of $\tilde{m}_1, \ldots, \tilde{m}_n$ are $\text{den}(m_1), \ldots, \text{den}(m_n) \in \mathbb{Z}$. However, $\text{lc}(\tilde{f}_2)$ is in general not an integer but an algebraic number.

5. It is very easy to tell if a prime $p$ is lc-bad or not, but we can not tell in advance if $p$ is fail, unlucky, or good. So we will end up calling the Euclidean algorithm mod $p$ with fail, unlucky, and good primes but never with lc-bad primes.
1.1 lc-bad primes

If \( f_1 = 5x + 1 \), \( f_2 = 5x - 1 \) and \( p = 5 \) then \( p \) satisfies our the definition of an lc-bad prime as well as the definition of a good prime. However, there are good reasons not to use any lc-bad prime. Take for example \( f_1 = f_2 = 5x + 1 \). Also, the proof of theorem 1 requires that \( p \) not be lc-bad.

Another example is \( L = \mathbb{Q}(\alpha) \), \( f_1, f_2 \in L[x] \) with \( \gcd g = x + \alpha^3 \), \( p = 5 \), and the minimal polynomial of \( \alpha \) is \( m = x^5 + x^4 + \frac{1}{3} x^3 - \frac{1}{3} \). Because of preprocessing, in the algorithm we work with \( \hat{m} = 5z^5 + 5z^4 + z^3 - 1 \). Modulo \( p = 5 \) this becomes \( z^3 + 4 \). If we used the prime \( p = 5 \), it is easy to give an example \( f_1, f_2 \) where the Euclidean algorithm mod \( p \) returns \( g \mod (5, \alpha^3 + 4) \) which is \( x + 1 \). But, viewing \( \alpha \) as a variable, \( g \not\equiv x + 1 \) mod 5.

For our algorithm, the best solution to the above problems is: never use an lc-bad prime.

1.2 Fail primes

Fail primes are primes for which the Euclidean algorithm mod \( p \) tries to divide by a zero divisor, in which case it returns “failed”. Take for example \( f_1 = x^2 - 1 \), \( f_2 = ax - a \) where \( a = 2^{1/5} + 5 \). Denote \( a \mod p \) as \( \overline{a} \). The Euclidean algorithm mod \( p \) will first try to make \( f_2 \mod p \) monic by multiplying it with \( 1/a \). But if \( N(a) \), the norm of \( a \), vanishes mod \( p \) then then \( \overline{\alpha} \) is zero or a zero-divisor, and the computation of \( 1/\overline{\alpha} \) fails. In this example \( N(a) = 53 \cdot 59 \) so the fail primes are 53 and 59.

The reason that in our terminology 53 and 59 are called fail primes and not lc-bad primes in the example (after all, the problem was caused by \( \text{lcm}(f_2) \mod p \)) is to indicate how these primes are discarded: We do not actively avoid these primes, instead, they “discard themselves” when the Euclidean algorithm mod \( p \) is called.

One can also construct examples where \( p \) is not lc-bad, \( \text{lcm}(f_2) \) is a unit mod \( p \), but \( p \) still divides \( \text{den}(g) \) (occasionally such \( p \) can be unlucky instead of fail). Take for example \( \alpha \) with minimal polynomial \( m = z^3 + 3z^2 - 46z + 1 \),

\[
    f_1 = x^3 - 2x^2 + (-2\alpha^2 + 8\alpha + 2)x - \alpha^2 + 11\alpha - 1, \quad f_2 = x^3 - 2x^2 - x + 1.
\]

The monic gcd is \( g = x - \frac{1}{91}\alpha^2 - \frac{21}{91}\alpha - \frac{50}{91} \). The denominator is \( \text{den}(g) = 91 = 7 \cdot 13 \). In this example, if \( p \in \{7, 13\} \) then \( p \) is not lc-bad and the leading coefficient of \( f_2 \) (as well as of \( f_1 \)) is a unit mod \( p \). Nevertheless, \( p \) can not be a good prime because \( p \mid \text{den}(g) \). In this type of example \( p \) must divide the discriminant. For this reason, Encarnacion [4] tests if the discriminant is 0 mod \( p \) and avoids such primes. However, even without
the discriminant-test, the primes \( p \in \{7, 13\} \) would still have been discarded at some point: The Euclidean algorithm mod \( p \) will calculate \( r_3 = f_1 \mod (p, f_2) \), try to make \( r_3 \) monic and fail because the leading coefficient of \( r_3 \), namely, \(-2x^2 + 8x + 3\), is a zero divisor mod \( p \).

Although one can generalize the discriminant-test to \( \mathbb{Q}(\alpha_1, \ldots, \alpha_n) \), see section 3, our algorithm does not use it because it makes no difference for the correctness of the algorithm. For an intuitive explanation see lemma 4 and for a proof see theorem 1.

### 1.3 Unlucky primes

Unlucky primes are not trivially detectable like lc-bad primes and do not “discard themselves” like fail primes do, but need to be detected and discarded nevertheless. Fortunately, Brown [3] showed how to do this in a way that is efficient and easy to implement: Whenever modular gcd’s do not have the same degree, keep only those of smallest degree and discard the others.

As an example, take \( f_1 = x^2 + (2\sqrt{5} + 1)x + 3 \), \( f_2 = x^2 - x - 1 \), \( g = x + (\sqrt{5} - 1)/2 \). Then the Euclidean algorithm mod 2 will return \( x^2 + x + 1 \), so \( p = 2 \) is an unlucky prime. But if \( f_1 = x^2 + \sqrt{5}x + 1 \), \( f_2 \) and \( g \) the same as before, then \( p = 2 \) is a fail prime.

### 1.4 Good primes

All but finitely many primes must be good. This is because if one would run the Euclidean algorithm in characteristic 0, it would be a finite computation, and so there can only be finitely many conditions on the primes and each condition only excludes finitely many primes (see lemma 5 each condition can be reduced to the form \( N \not\equiv 0 \mod p \) where \( N \) is some nonzero integer).

Of course we will not run the Euclidean algorithm in characteristic 0, so we can not use this as a criterion to find good primes. To guarantee correctness of the algorithm, just as in Brown’s algorithm, all we need to do is to avoid the lc-bad primes, which is easy to do.

### 1.5 Motivation for the algorithm

The goal of this paper is to present an efficient modular GCD algorithm over a field \( L \) that consists of multiple extensions over \( \mathbb{Q} \). Suppose the largest numerator or denominator in \( g \) is \( c \). To reconstruct \( g \) by computing \( g \mod P = p_1 \cdots p_m \) using primes \( p_1, \ldots, p_m \), if we want \( \log(P) = O(\log(c)) \), that
is, if we want the number of primes used to be proportional to the size of
the coefficients in \( g \), then we are forced to

1. Not use a primitive element to convert to a single extension, which is
   expensive and can cause a blowup in the size of the coefficients. This
   problem is well known, e.g. see [1].

2. Not invert \( \text{lc}(f_2) \), which can also cause a blowup, and can also be more
   expensive than computing \( g \).

3. Use rational reconstruction, because \( \gamma \) can be much larger than \( \text{den}(g) \),
   and the defect bound (usually the (reduced) discriminant) is generally
   too large.

Encarnacion's paper confirms each of these. As for item 1, his paper deals
only with a single extension, but he does illustrate that modifying that
extension (making \( \alpha_1 \) an algebraic integer) is not efficient. But if modifying
one extension \( \alpha_1 \) is not efficient, then modifying \( n \) extensions (replacing it
by a primitive element) is certainly not efficient.

In summary, Encarnacion gave the best known algorithm for a single
extension, and our goal is to generalize it to multiple extensions, without
using a primitive element because that could be devastating for the efficiency.
A technical difficulty is how to generalize the discriminant test, which we
did in section 3. It turned out, however, that this test is not necessary, it can
be omitted. So we not only generalize Encarnacion's algorithm, we simplify
it as well.

In this paper we only treat univariate polynomials \( f_1, f_2 \in L[x] \), but our
implementation handles the multivariate case as well.

2 The Euclidean algorithm over a ring

Let \( \alpha_1, \ldots, \alpha_n \) be algebraic numbers. Denote \( L_i = \mathbb{Q}(\alpha_1, \ldots, \alpha_i) \) and \( L = L_n \). Let \( d_i \) be the degree of \( \alpha_i \) over \( \mathbb{Q}(\alpha_1, \ldots, \alpha_{i-1}) \). The dimension of \( L \) as
a \( \mathbb{Q} \)-vector space is \( d_s := d_1 \cdots d_n \). A basis of \( L \) is:

\[
M := \left\{ \prod_{i=1}^{n} \alpha_i^{e_i} \mid 0 \leq e_i < d_i \right\}.
\]

Let \( \tilde{R} \) be the set of all \( \mathbb{Z} \)-linear combinations of \( M \) and let \( \tilde{R}_i = \tilde{R} \cap L_i \).
Let \( m_i \) be the minimal polynomial of \( \alpha_i \) over \( L_{i-1} \). The degree of \( m_i \) is \( d_i \),
\( m_i \) is monic (the leading coefficient is \( \text{lc}(m_i) = 1 \)) and \( m_i(\alpha_i) = 0 \). The
coefficients of \( m_i \) are in \( L_{i-1} \). Let \( l_i \) be the smallest positive integer such that the coefficients of \( l_im_i \) are in \( \tilde{R}_{i-1} \). Denote \( \mathbb{F}_p = \mathbb{Z}/p\mathbb{Z} \) and \( l_s = l_1 \cdots l_n \).

In general \( \tilde{R} \) is not a ring. For example, \( \alpha_1 \in \tilde{R} \), but \( \alpha_1^{d_1} \) is not in \( \tilde{R} \) unless \( l_1 = 1 \). When \( a, b \in \tilde{R} \), to compute the product \( ab \in L \) we have to replace \( \alpha_1, \ldots, \alpha_n \) by variables \( z_1, \ldots, z_n \), then multiply \( a,b \) as polynomials, and after that take the remainder modulo the polynomials \( m_1(z_1), \ldots, m_n(z_n) \). During this computation we only divide by \( l_1, \ldots, l_n \). Hence, if \( k \) is a sufficiently large integer, then \( l_s^ka \in \tilde{R} \) for all \( a, b \in \tilde{R} \).

If \( a \in L \) then define the denominator of \( a \) as the smallest positive integer \( \text{den}(a) \) such that \( \text{den}(a)a \in \tilde{R} \). Note that \( \tilde{R} \), and hence \( \text{den}(a) \), depends on the choice of \( \alpha_1, \ldots, \alpha_n \). For example, if \( \alpha_1 = \sqrt{2} \) and \( a = \frac{1}{2}\alpha_1 \) then \( \text{den}(a) = 2 \). For \( a \in L \) one has \( a \in \tilde{R} \iff \text{den}(a) = 1 \), in particular \( \text{den}(0) = 1 \). Define

\[
R_p = \{ a \in L \mid \text{den}(a) \neq 0 \text{ mod } p \} 
\]

\[
= \left\{ \frac{a}{m} \mid a \in \tilde{R}, m \in \mathbb{Z}, m \neq 0 \text{ mod } p \right\}.
\]

If \( a, b \in L \) then \( \text{den}(ab) \) divides \( \text{den}(a)\text{den}(b)l_s^k \) for some \( k \). Hence, if \( p \nmid l_s \) then \( R_p \) is a ring. We will always assume that \( p \) does not divide \( l_s \) so that \( R_p \) is a ring (if \( p \mid l_s \) then \( p \) is an lc-bad prime). Denote

\[
\mathbb{Z}(p) = R_p \cap \mathbb{Q} = \left\{ \frac{a}{m} \mid a, m \in \mathbb{Z}, m \neq 0 \text{ mod } p \right\}.
\]

Then \( R_p \) is a \( \mathbb{Z}(p) \)-module with basis \( M \). Define

\[
\tilde{R} = R_p/pR_p.
\]

If \( a \in R_p \) then we use the notation \( \overline{a} \), or also \( a \text{ mod } p \), for the image of \( a \) in \( \tilde{R} \). If \( a \in L \), then (primes that divide \( l_s \) are always excluded)

\( \overline{a} \) is defined \( \iff a \in R_p \iff p \nmid l_s\text{den}(a) \).

If \( \overline{a} \) is defined we will say that \( a \) can be reduced mod \( p \).

Now \( \tilde{R} \) is a ring and also an \( \mathbb{F}_p \)-vector space with basis \( M \) mod \( p \). We can do the following identifications:

\[
R_p = \tilde{R} \otimes_{\mathbb{Z}} \mathbb{Z}(p), \quad L = \tilde{R} \otimes_{\mathbb{Z}} \mathbb{Q}, \quad \text{and} \quad \tilde{R} = \tilde{R} \otimes_{\mathbb{Z}} \mathbb{F}_p
\]

If \( a \in L \) then \( a \) is a unit in \( R_p \) if and only if both \( a \) and \( 1/a \) are in \( R_p \) (whenever we write \( 1/a \) it is implicitly assumed that \( a \neq 0 \)). This is equivalent to \( p \nmid l_s\text{den}(a)\text{den}(1/a) \). If \( a \in L \) we will call \( a \) a unit mod \( p \) if \( a \in R_p \) and \( \overline{a} \) is a unit in \( \tilde{R} \). The following lemma shows that these two notions are equivalent.
Lemma 1. The map \( a \mapsto \overline{a} \) is a ring homomorphism from \( R_p \) to \( \overline{R} \). If \( a \in R_p \) then \( a \) is a unit in \( R_p \) if and only if \( \overline{a} \) is a unit in \( \overline{R} \).

Proof: The first statement is true because \( \overline{R} = R_p/pR_p \) and \( pR_p \) is an ideal in \( R_p \). If \( a \) is a unit in \( R_p \) then \( a \) and \( 1/a \) are in \( R_p \), hence \( \overline{a} \) and \( \overline{1/a} \) are defined, and since \( a \mapsto \overline{a} \) is a ring homomorphism one sees that \( \overline{1/a} \) is the inverse of \( \overline{a} \). Hence \( \overline{a} \) is a unit in \( \overline{R} \).

Conversely, assume \( \overline{a} \) is a unit. Then \( a \neq 0 \) so we can take \( b := 1/a \in L \). To finish the proof we need need to show that \( b \in R_p \). Take the smallest integer \( k \) for which \( c := bp^k \in R_p \). Since \( k \) is minimal, we have \( \overline{c} \neq 0 \) but then \( \overline{pc} \) is the product of a unit and a nonzero element in \( \overline{R} \) and hence nonzero. But \( \overline{a} \) equals \( abp^k = p^k \) so \( p^k \neq 0 \), hence \( k = 0 \), so \( b \in R_p \) and \( a \) is invertible in \( R_p \).

If \( f \in L[x] \) then the denominator \( \text{den}(f) \) is defined as the smallest positive integer such that \( \text{den}(f) f \in \overline{R}[x] \). Now \( f \in R_p[x] \) if and only if \( p \nmid \text{den}(f)_* \). The polynomial \( \overline{f} \) is the image of \( f \) in \( \overline{R}[x] \), and is defined if and only if \( f \in R_p[x] \), in which case we will say that \( f \) can be reduced mod \( p \). Furthermore, if \( f \) and \( \overline{f} \) have the same degree (when \( \text{lc}(f) \) is nonzero mod \( p \)) then we will say that \( f \) reduces properly mod \( p \). If \( p \) is not an lcbad prime it means that \( f_1, f_2 \) can be reduced mod \( p \), and that \( f_2 \) reduces properly mod \( p \).

Let \( 0 \leq i \leq j \leq n \) and \( a \in L_j \). Multiplication by \( a \) is an \( L_i \)-linear map \( \psi : L_j \to L_i \). The characteristic polynomial \( \text{cp}_i^j (a) \in L_i[x] \) of \( a \) over the extension \( L_j : L_i \) is defined as the characteristic polynomial of this linear map. The trace \( \text{Tr}_i^j (a) \) of \( a \) over \( L_j : L_i \) is the trace of \( \psi \) and the norm \( N_i^j (a) \) of \( a \) over \( L_j : L_i \) is the determinant of \( \psi \). Whenever we do not mention the extension \( L_j : L_i \) it is assumed to be \( L : \mathbb{Q} \) (so \( i = 0 \) and \( j = n \)) in which case we write \( \text{Tr}(a), N(a), \text{cp}(a) \). Now the integral closure of \( \mathbb{Z} \) in \( L \) is

\[
\mathcal{O} = \{ a \in L \mid \text{cp}(a) \in \mathbb{Z}[x] \}.
\]

This is a ring (see [5]), and the elements of \( \mathcal{O} \) are called the algebraic integers in \( L \). We will use the following notation for the integral closure of \( \mathbb{Z}_p \)

\[
\mathcal{O}_p = \{ a \in L \mid \text{cp}(a) \in \mathbb{Z}_p[x] \}.
\]

Suppose \( a \in L \) and \( m = \text{den}(\text{cp}(a)) \). Then by definition \( a \in \mathcal{O}_p \) if and only if \( m \neq 0 \) mod \( p \). The characteristic polynomial of \( ma \) is in \( \mathbb{Z}[x] \), hence \( ma \in \mathcal{O} \) and hence

\[
\mathcal{O}_p = \left\{ a \frac{m}{m} \mid a \in \mathcal{O}, \; m \in \mathbb{Z}, \; m \neq 0 \text{ mod } p \right\}.
\]
Lemma 2 If $0 \leq i \leq j \leq n$ and $a \in \mathcal{O}_p \cap L_j$ then $a$ is a unit in $\mathcal{O}_p$ if and only if $N^j_i(a)$ is a unit in $\mathcal{O}_p$. In particular, $a \in \mathcal{O}_p$ is a unit if and only if $N(a) \in \mathbb{Q}$ is a unit in $\mathbb{Z}(p)$; in other words, both numerator and denominator of $N(a)$ are not divisible by $p$. The same is also true for $R_p$.

Remark: If $p \nmid l_*$ then $R_p \subseteq \mathcal{O}_p$ and the lemma implies that if $a \in R_p$ and $1/a \in \mathcal{O}_p$ then $1/a \in R_p$.

Proof: The $L_i$-linear map $\psi : L_j \rightarrow L_j$ that corresponds to multiplication by $a$ is defined over $\mathcal{O}_p$, i.e. the entries the matrix of $\psi$ are in $\mathcal{O}_p$. If $N^j_i(a)$, the determinant of $\psi$, is a unit in $\mathcal{O}_p$ then the matrix is invertible over $\mathcal{O}_p$. So then $\psi^{-1}(1) \in \mathcal{O}_p$, so $1/a \in \mathcal{O}_p$. Conversely, if $a$ is invertible in $\mathcal{O}_p$ then $\psi$ is an invertible linear map, so its determinant must be a unit.

Now $N(a) = N^0_i(a) \in L_0 = \mathbb{Q}$ and $\mathbb{Q} \cap \mathcal{O}_p = \mathbb{Z}(p)$ so the second statement follows. The proof for $R_p$ is the same, although as always $p$ must not divide $l_*$ so $R_p$ is a ring.

Note that one can check if $a \in R_p$ is invertible, and if so, compute its inverse, with linear algebra over $\mathbb{Z}(p)$ or over its field of fractions $\mathbb{Q}$. The matrix of the system to be solved is the matrix of $\psi$. The same also holds for $\pi \in \overline{\mathbb{F}}$, whenever it is invertible, its inverse can be computed with linear algebra over $\mathbb{F}_p$. But instead of solving linear equations, we will use the extended Euclidean algorithm to calculate inverses in $\overline{\mathbb{F}}$. However, this can increase the number of fail primes because the calculation can fail even if $\pi$ is invertible. This is not a serious problem because the number of fail primes will still be finite (see section 1.4).

In the following, let $\mathcal{R}$ be a commutative ring with identity $1 \neq 0$. For a univariate polynomial $f \in \mathcal{R}[x]$ define monic($f$) as follows: If $f = 0$ then monic($f$) = 0. If $f \neq 0$ and if the leading coefficient $\text{lc}(f) \in \mathcal{R}$ of $f$ is a unit, then define monic($f$) = $\text{lc}(f)^{-1} f$. If $f \neq 0$ and $\text{lc}(f)$ is not a unit then define monic($f$) = “failed”.

If $f_1, f_2 \in \mathcal{R}[x]$ then the monic $\text{gcd}$ is defined as a polynomial $g \in \mathcal{R}[x]$ such that $g = \text{monic}(g)$ and for every polynomial $h$ one has: $h \mid f_1$ and $h \mid f_2$ if and only if $h \mid g$. It is easy to show that if a monic gcd of $f_1, f_2$ exists, then it is unique. The well-known Euclidean algorithm over $\mathcal{R}$ works as follows.

Euclidean algorithm.

Input: a list $(f_1, f_2)$ of two univariate polynomials with coefficients in $\mathcal{R}$.

Output: Either a message “failed” or the monic gcd.
1. Set \( r_1 = f_1, r_2 = f_2, i = 2 \).
2. If \( r_2 = 0 \) then set \( r_1 = \text{monic}(r_1) \). If \( r_1 = \text{"failed"} \) then return "failed".
3. If \( r_i = 0 \) then return \( r_{i-1} \).
4. Set \( r_i = \text{monic}(r_i) \). If \( r_i = \text{"failed"} \) then return "failed".
5. Set \( r_{i+1} \) to be the remainder of \( r_{i-1} \) divided by \( r_i \).
6. Set \( i = i + 1 \) and go back to Step 3.

**Remark on a shortcut:** Suppose that \( r_i \) in step 3 is a nonzero constant. Some implementations of the Euclidean algorithm over a field will then take a shortcut: stop the computation, the output is 1. Over a ring we should not use this shortcut because that would invalidate lemma 3 below. This plays a role because our algorithm will not test if \( p \) divides the discriminant. We may only use the shortcut if \( r_i \) is a unit. For \( r_i \in R \) we can test that efficiently by computing \( N(r_i) \mod p \) (see lemmas 1,2).

Denote \( \gcd_R(f_1, f_2) \) as the output of this algorithm. If \( \gcd_R(f_1, f_2) \neq \text{"failed"} \) then the sequence of polynomials \( r_1, \ldots, r_m \) with \( r_{m-1} \neq 0, r_m = 0 \), is called the monic polynomial remainder sequence of \( f_1, f_2 \).

**Lemma 3** If \( g = \gcd_R(f_1, f_2) \) and \( g \neq \text{"failed"} \) then the ideal \( (r_i-1, r_i) = R[x]r_i-1 + R[x]r_i \) remains the same during each step. In particular \( (f_1, f_2) = (g) \) which implies:

1. There exist \( s, t \in R[x] \) such that \( g = sf_1 + tf_2 \).
2. \( f_1 \) and \( f_2 \) are divisible by \( \gcd(g) \).
3. \( g \) is the monic gcd of \( f_1 \) and \( f_2 \).

**Proof:** When we make \( r_i \) monic, we divide by a unit, which does not change the ideal. In step 6 we increase \( i \) so we must show that \( (r_{i-1}, r_i) = (r_i, r_{i+1}) \) which is clear because \( r_{i+1} \) is the remainder of \( r_{i-1} \) modulo \( r_i \). Hence \( (f_1, f_2) = (r_1, r_2) = (r_{m-1}, r_m) = (g, 0) = (g) \). So \( g \in (f_1, f_2) \) which is part 1, \( f_1, f_2 \in (g) \) which is part 2. Finally, every \( h \) that divides both \( f_1 \) and \( f_2 \) divides any element of \( (f_1, f_2) \) in particular it divides \( g \). Since \( g \) is monic it satisfies precisely the definition of the monic gcd.

**Remark:** If \( \gcd_R(f_1, f_2) \neq \text{"failed"} \) then the extended Euclidean algorithm, which calculates \( g \) as well as \( s, t \) will not fail either.
Let $d = \text{GCD}_{R}(f_1, f_2)$ be the output of the Euclidean algorithm. If all leading coefficients during the computation are units then the algorithm succeeds, the monic gcd exists and equals $d = r_{m-1}$. If there is no monic gcd in $R[x]$ then $d =$ “failed”. If a monic gcd $g$ does exist then it is not necessarily true that the algorithm will find it; the output $d$ is then either $g$ or “failed”. A situation where the output is “failed” even when a monic gcd exists is the following:

**Lemma 4** Suppose $p \nmid t_s$ and $f_1, f_2 \in R_p[x] \subseteq O_p[x]$. Suppose a monic gcd $g \in O_p[x]$ exists and that $g \notin R_p[x]$. Then $\text{GCD}_{O_p}(f_1, f_2) =$ “failed”.

**Remark:** The lemma gives a hint that a discriminant test might not necessary because if $p$ is not lc-bad then the worst that can happen is that $p$ is fail or unlucky. Theorem 1 below shows that this is indeed true.

**Proof:** Since $\text{GCD}_{R_p}(f_1, f_2) =$ “failed”, when we run the Euclidean algorithm over $R_p$ we will encounter a leading coefficient in $R_p$ that is not a unit in $R_p$. But according to the remark after lemma 2, if $a \in R_p$ is not a unit in $R_p$ then it is also not a unit in $O_p$ and hence the algorithm fails over $O_p$ as well.

If the ring $R$ in the Euclidean algorithm is a field $L$, then the output is never “failed”, so $\text{GCD}_{L}(f_1, f_2)$ is always the monic gcd of $f_1, f_2 \in L[x]$.

**Lemma 5** Suppose $f_1, f_2 \in L[x]$ and $r_1, \ldots, r_m \in L[x]$ is the monic polynomial remainder sequence. Suppose $\text{lc}_1, \ldots, \text{lc}_{m-1} \in L$ were the leading coefficients that we divided by in steps 2 and 4. For all but finitely many primes the following holds:

1. $f_1, f_2 \in R_p[x]$, and $\text{lc}_1, \ldots, \text{lc}_{m-1}$ are units in $R_p$.
2. $r_1, \ldots, r_m \in R_p[x]$ and $\overline{r_1}, \ldots, \overline{r_m}$ is the monic polynomial remainder sequence of $\overline{f_1}, \overline{f_2}$.
3. $p$ is a good prime which means: The monic gcd of $\overline{f_1}, \overline{f_2}$ exists, will be found by the Euclidean algorithm, and equals $\overline{g}$ where $g \in L[x]$ is the monic gcd of $f_1, f_2$.

**Proof:** Part 1 holds for all primes that do not divide any of the following: $t_s, \text{den}(f_1), \text{den}(f_2), \text{den}(\text{lc}_i), \text{den}(1/\text{lc}_i)$ for $i < m$. Since these are finitely many integers, all nonzero, we see that part 1 holds for all but finitely many primes. The only divisions in the Euclidean algorithm are divisions by $\text{lc}_i$, so if the input is in $R_p[x]$ and all $\text{lc}_i$ are units in $R_p$, then all polynomials in the
GCDₜ(f₁, f₂) computation are in Rₚ[x]. Induction shows that r₁, ..., rₘ is precisely the monic polynomial remainder sequence of f₁, f₂, so part 2 follows from part 1. Part 3 follows from part 2.

Since we will only run the Euclidean algorithm in R[x] for various primes p, and not in L[x], we do not know the values of lcᵢ. So the lemma does not tell us which primes are good, it only says that all but finitely many primes are good. We now investigate the relation between \( \text{GCD}_{\pi}(\overline{f₁}, \overline{f₂}) \) and \( \text{GCD}_{L}(f₁, f₂) \) when p is not an lc-bad prime.

**Theorem 1** Let \( f₁, f₂ \in L[x] \) and let \( g \in L[x] \) be the monic gcd. Assume \( p \nmid \text{den}(f₁)\text{den}(f₂), f₂ \neq 0 \) and \( \text{lc}(f₂) \neq 0 \mod p \), so p is not an lc-bad prime. Let \( d = \text{GCD}_{\pi}(\overline{f₁}, \overline{f₂}) \). If \( d \neq \text{failed} \) then

\[
\deg(d) \geq \deg(g).
\]

Furthermore, if \( \deg(d) = \deg(g) \) then \( g \) reduces property \( \mod p \) and \( d = \overline{g} \).

**Remark:** The theorem says that if p is not lc-bad then p is either fail, unlucky, or good. This implies that if lc-bad primes are avoided then the modular GCD algorithm is correct.

**Proof:** \( \text{lc}(f₂) \neq 0 \mod p \), so if we assume \( d \neq \text{failed} \) then \( \text{lc}(f₂) \) must be a unit \( \mod p \), see step 4 in the Euclidean algorithm. There exist (see lemma 3) \( s₀, t₀ \in Rₚ[x] \) such that

\[
\overline{s₀f₁ + t₀f₂} = d.
\]

Now take a monic polynomial \( d₀ \in Rₚ[x] \) such that \( d = \overline{d₀} \). Then we have

\[
s₀f₁ + t₀f₂ \equiv \overline{d₀} \mod p.
\]

We will apply Hensel lifting to increase the modulus \( p \) to a higher power of \( p \). Define (starting with \( i = 1 \))

\[
hᵢ = (sᵢ₋₁f₁ + tᵢ₋₁f₂ - dᵢ₋₁)/pⁱ \in Rₚ[x]
\]

and let \( qᵢ, rᵢ \in Rₚ[x] \) be the quotient and remainder of \( hᵢ \) divided by \( d₀ \) (this division works because \( d₀ \) is monic). Then define

\[
sᵢ = sᵢ₋₁ - pⁱqᵢs₀, \quad tᵢ = tᵢ₋₁ - pⁱqᵢt₀, \quad \text{and} \quad dᵢ = dᵢ₋₁ + pⁱrᵢ.
\]

Then

\[
sᵢf₁ + tᵢf₂ \equiv dᵢ \mod p^{i+1}.
\]
Now \( \tilde{s}_i, \tilde{t}_i \) can have higher degrees than \( s_{i-1}, t_{i-1} \). To remedy this, do the following. For \( j \in \{1, 2\} \) denote \( f_{j,d} \in R_p[x] \) as a polynomial whose modular image equals \( \overline{f_j} / d \). Take \( q_i r_0 \mod p \), and divide it by \( \overline{f_{2,d}} \in \overline{R}[x] \). This division works because the leading coefficient of \( \overline{f_{2,d}} \) is \( \text{lcm}(f_2) \) mod \( p \), which is invertible. Take \( q, r \in R_p[x] \) such that \( \overline{q}, \overline{r} \) are the quotient and remainder of this division. Take \( q, r \) in such a way that they have the same degree as \( \overline{q}, \overline{r} \). Then define

\[
\tilde{s}_i = s_{i-1} - p^i r, \quad \text{and} \quad \tilde{t}_i = t_{i-1} - p^i(q_i t_0 + q f_{1,d}),
\]

and we still have

\[
s_i f_1 + t_i f_2 = d_i \mod p^{i+1}.
\]

We can now increase \( i \) and do the next Hensel step, and continue in this way. Because \( \deg(r) < \deg(\overline{f_{2,d}}) \), the degree of \( s_i \) will be bounded as \( i \) increases. The degrees of \( t_i \) and \( d_i \) are also bounded. So when \( i \to \infty \), the limit \( \hat{s}, \hat{t}, \hat{d} \) of \( s_i, t_i, d_i \) exists in the ring \( \hat{R}_p[x] \) defined below.

Denote \( \hat{\mathbb{Z}}_p \) as the ring of \( p \)-adic integers, \( \hat{\mathbb{Z}}_p \) is the completion of \( \mathbb{Z}_p \) with respect to the \( p \)-adic valuation norm. Let \( \hat{\mathbb{Q}}_p \) be the field of \( p \)-adic numbers, the field of fractions of \( \hat{\mathbb{Z}}_p \). Denote \( \hat{L}_p = R_p \otimes_{\mathbb{Z}_p} \hat{\mathbb{Q}}_p = L \otimes_{\mathbb{Q}} \hat{\mathbb{Q}}_p \). This is in general not an integral domain because minimal polynomials can become reducible when one replaces \( \mathbb{Q} \) by a larger field \( \hat{\mathbb{Q}}_p \). Denote \( \hat{R}_p = R_p \otimes_{\mathbb{Z}_p} \hat{\mathbb{Z}}_p \).

Now \( \hat{R}_p \) and \( L \) can be viewed as subrings of \( \hat{L}_p \) and

\[
R_p = \hat{R}_p \bigcap L \tag{5}
\]

After doing infinitely many Hensel steps we find \( \hat{s}, \hat{t}, \hat{d} \in \hat{R}_p[x] \) such that

\[
\hat{s} f_1 + \hat{t} f_2 = \hat{d}.
\]

Now \( \hat{d} \) is monic and \( \deg(\hat{d}) = \deg(\hat{d}_0) = \deg(d) \) because the \( p^i r_i, i = 1, 2, \ldots \), that we added to \( d_0 \) have smaller degree than \( d_0 \). The polynomials \( f_1, f_2 \) are elements of \( L[x] \supseteq \hat{L}_p[x] \). Hence \( \hat{s} f_1 + \hat{t} f_2 \), which equals \( \hat{d} \), is also an element of \( \hat{L}_p[x] \). But \( \hat{d} \neq 0 \) so

\[
\deg(\hat{d}) = \deg(\hat{d}) \geq \deg(g).
\]

If the degrees are the same then \( \hat{d} = g \) because \( g \) is the only monic element of \( \hat{L}_p[x] \) of that degree. Equation (5) then implies \( g \in R_p[x] \) (recall that \( \hat{d} \in \hat{R}_p[x] \) and \( g \in L[x] \)). So \( g \) can be reduced mod \( p \). Hence \( g \) reduces properly mod \( p \) because it is monic. The theorem now follows because \( d \) equals \( d \mod p \), which equals \( g \mod p \).
3 The reduced discriminant

One has \( l_1 \alpha_1 \in \mathcal{O} \). The degree of \( m_2 \) viewed as polynomial in \( \alpha_1 \) is less than \( d_1 \) and so \( l_1^{d_1-1} m_2 \) is a polynomial with coefficients in \( \mathcal{O} \). The leading coefficient is \( l_1^{d_1-1} l_2 \) and hence \( l_1^{d_1-1} l_2 \alpha_2 \in \mathcal{O} \). Repeating this we see that there exists a positive integer \( k \) such that \( \gamma_i := l^k \alpha_i \in \mathcal{O} \) for all \( i \). Then \( \mathbb{Z}[\gamma_1, \ldots, \gamma_n] \subseteq \bar{R} \cap \mathcal{O} \).

An element \( D \in L \) is called a defect of \( \bar{R} \) if \( D \mathcal{O} \subseteq \bar{R} \). The discriminant of \( \mathbb{Z}[\gamma_1, \ldots, \gamma_n] \) is an example of an integer defect (i.e., a defect in \( \mathbb{Z} \)). In this section we will present a defect \( D \in L \) that is generally not an integer. The following lemma shows how one can one can obtain an integer defect from a defect.

**Lemma 6** If \( D \in L \) is a defect then \( l_1^k \text{den}(1/D) \) is an integer defect for some integer \( k \).

**Proof:** Denote \( d = \text{den}(1/D) \) and \( a = d/D \), then \( a \in \bar{R} \) by definition of \( \text{den}(1/D) \). Now

\[
d \mathcal{O} = a D \mathcal{O} \subseteq a \bar{R}
\]

and this, multiplied by \( l^k \) for some \( k \), is a subset of \( \bar{R} \).

**Lemma 7** Let \( p \) be a prime that does not divide \( l_1 \). Then \( R_p \subseteq \mathcal{O}_p \). If \( D \) is a defect and \( D \) is a unit in \( \mathcal{O}_p \) then \( R_p = \mathcal{O}_p \), so then \( R_p \) is integrally closed.

**Proof:** \( R_p \) is generated over \( \mathbb{Z}_p \) by \( \alpha_1, \ldots, \alpha_n \), and \( \mathbb{Z}_p \subseteq \mathcal{O}_p \). Since \( l^k \alpha_i \in \mathcal{O} \subseteq \mathcal{O}_p \) and \( l_1 \) is a unit in \( \mathcal{O}_p \) we have \( \alpha_i \in \mathcal{O}_p \) and hence \( R_p \subseteq \mathcal{O}_p \).

If \( D \) is a defect then \( D \mathcal{O} \subseteq \bar{R} \) and hence \( D \mathcal{O}_p \subseteq R_p \), see equations (2) and (4) in section 2. But if \( D \) is a unit in \( \mathcal{O}_p \) then \( D \mathcal{O}_p = \mathcal{O}_p \) so the lemma follows.

**Lemma 8** Suppose a defect \( D \) is a unit in \( \mathcal{O}_p \), \( p \nmid l_1 \) and \( f_2 \in R_p[x] \).

Suppose that \( \text{lc}(f_2) \) is a unit mod \( p \). Then any monic factor \( g \in L[x] \) of \( f_2 \)

is in \( R_p[x] \).

**Proof:** The leading coefficient of \( f_2 \in R_p[x] \) is invertible, and according to lemma 7 the ring \( R_p \) is integrally closed. Then we can apply Gauss’ lemma: Any monic factor \( g \in L[x] \) (\( L \) is the field of fractions of \( R_p \)) of \( f_2 \) is in \( R_p[x] \).

**Remark:** One can simultaneously test if both \( D \) and \( \text{lc}(f_2) \) are units by testing if \( \text{lc}(f_2)D \) is a unit, which can be done by computing \( N(\text{lc}(f_2)D) \)
mod \( p \), see lemma 2 and the remark after lemma 9. If so, then lemma 8 says that any monic factor \( g \in L[x] \) of \( f_2 \) is in \( R_p[x]\), in particular the monic gcd of \( f_1, f_2 \) is in \( R_p[x] \) where \( f_1 \) is any other element of \( L[x] \).

Recall that \( m_i \) is the minimum polynomial of \( \alpha_i \) over \( L_{i-1} \). Define

\[
\Delta_i := m'_i(\alpha_i) \in L_i \quad \text{and} \quad \Delta := \Delta_1 \cdots \Delta_n \in L
\]

where \( m'_i \) is the derivative of \( m_i \).

**Lemma 9** There is an integer \( k \) such that \( \mathcal{D} := t^k \Delta \) is a defect.

**Remark:** Note that \( \Delta \) is a unit in \( \mathcal{O}_p \) if and only if \( \mathcal{D} \) is a unit in \( \mathcal{O}_p \) because we always assume \( p \nmid \ell \). Since \( \Delta \) is the product of \( \Delta_1, \ldots, \Delta_n \in \mathcal{O}_p \) it follows that \( \Delta \) is a unit iff each \( \Delta_i \) is a unit. This leads to the test below. In the test, to save computation time, we delay multiplying with \( \Delta_i \) until we reach an expression that does not contain \( \alpha_{i+1}, \ldots, \alpha_n \). We also avoid multiplications in characteristic 0 (so we do not compute \( \Delta \in L \)).

To compute \( N_{i-1}(a) \), replace \( \alpha_i \) by a variable \( z_i \), and eliminate this variable from \( a \) by computing \( \text{res}_a(m_i(z_i), a) \). Note that this can introduce additional fail primes, because the resultant algorithm mod \( p \), which is very similar to the Euclidean algorithm mod \( p \), fails when it attempts to divide by a zero divisor.

**Test if \( \mathcal{D} \) is invertible mod \( p \):** Assume \( p \nmid \ell \).

- Step 1. Let \( a = \Delta_n \mod p \).
- Step 2. If we want to test \( \text{lc}(f_2) \) as well then multiply \( a \) by \( \text{lc}(f_2) \mod p \).
- Step 3. Let \( i = n \).
- Step 4. Set \( a = N_{i-1}(a) \mod p \). If “failed” then return “failed”.
- Step 5. If \( a = 0 \) then return “not invertible”.
- Step 6. Set \( i = i - 1 \). If \( i = 0 \) then return “invertible”.
- Step 7. Multiply \( a \) by \( \Delta_i \mod p \), and go back to step 4.

**Proof of lemma 9:** Denote \( \mathcal{O}(i) = \mathcal{O} \cap L_i \) and

\[
\mathcal{\tilde{O}}(i) = \sum \mathcal{O}(i) \alpha_{i+1}^{e_{i+1}} \cdots \alpha_n^{e_n}.
\]

where the sum taken over all tuples \( e_{i+1}, \ldots, e_n \) with \( e_j < d_j \). So \( \mathcal{\tilde{O}}(i) \) is a \( \mathcal{O}(i) \)-module generated by monomials \( \alpha_{i+1}^{e_{i+1}} \cdots \alpha_n^{e_n} \). In particular \( \mathcal{\tilde{O}}(0) = \mathcal{R} \) and \( \mathcal{\tilde{O}}(n) = \mathcal{O} \). Now lemma 10 below shows that

\[
\Delta_i t^k_i \mathcal{O}(i) \subseteq \sum_{e=0}^{d_i-1} \mathcal{O}(i-1) \alpha_i^e
\]
for some integer $k_i$ and hence
\[ \Delta_{n^k} \tilde{O}(i) \subseteq \tilde{O}(i - 1). \]

Then
\[ \Delta_1 \cdots \Delta_{n^k} \tilde{O}(n) \subseteq \tilde{O}(0) \]
and the lemma follows.

The proof of the following lemma comes from [2] (see also page 119 in [5]).

**Lemma 10** Let $K$ be a number field, $\alpha$ algebraic of degree $d$ over $K$ and $L = K(\alpha)$. Denote $\mathcal{O}_K$ and $\mathcal{O}_L$ as the algebraic integers in $K$ and $L$. Let $m$ be the minimum polynomial of $\alpha$ over $K$. Let $l$ be a positive integer for which $l\alpha$ is an algebraic integer. Then there exists an integer $k$ such that for every $\beta \in \mathcal{O}_L$ there exists a polynomial $g$ of degree $< d$ and coefficients in $\mathcal{O}_K$ such that
\[ l^k m'(\alpha) \beta = g(\alpha). \]

**Proof:** Let $L'$ be a Galois extension of $L$ and let $\alpha^{(j)}$, $j = 1, \ldots, d$ be the conjugates of $\alpha$ over $L : K$, i.e. $\{\alpha^{(1)}, \ldots, \alpha^{(d)}\}$ is the orbit of $\alpha$ under the Galois group of $L'$ over $K$. We may assume $\alpha^{(1)} = \alpha$. Define $\beta^{(j)}$, $j = 1, \ldots, d$ in the same way. Now set $k = d - 1$ and
\[ g(x) = \sum_{j=1}^{d} \beta^{(j)} l^k \frac{m(x)}{x - \alpha^{(j)}}. \]

The Galois group of $L'$ over $K$ only permutes the terms, hence $g(x)$ is invariant: $g(x) \in K[x]$. Furthermore, each term is a polynomial in $x$ of degree $d - 1$ so the degree of $g$ is less than $d$. Denote $\mathcal{O}_{L'}$ as the algebraic integers in $L'$. Now $\beta^{(j)}$, $l\alpha^{(j)} \in \mathcal{O}_{L'}$. Furthermore
\[ l^k \frac{m(x)}{x - \alpha^{(j)}} = \prod_{h \neq j} (lx - l\alpha^{(h)}) \in \mathcal{O}_{L'}[x] \]
and hence $g(x) \in \mathcal{O}_{L'}[x] \cap K[x] = \mathcal{O}_K[x]$. Now $g(\alpha) = \beta^k m'(\alpha)$ and the lemma follows.

If $l_s = 1$ (so $\alpha_1, \ldots, \alpha_n \in \mathcal{O}$) then we can generalize the reduced discriminant from [2] to the multiple extensions case as follows:
\[
\text{reduced discriminant} = \text{rdisc}(\alpha_1, \ldots, \alpha_n) := \text{den}(1/\Delta)
\]
(see lemma 6). Even though it contains the same prime factors, the reduced discriminant can be substantially smaller than the discriminant, see [2]. This is useful for algorithms for computing $\mathcal{O}$ because such algorithms factor the (reduced) discriminant, and factoring integers can be very expensive. First factor $\text{rdisc}(\alpha_1, \ldots, \alpha_t)$, where $i < n$ because it divides $\text{rdisc}(\alpha_1, \ldots, \alpha_n)$.

**Example:** Let $\alpha_1 = \sqrt{5}$, $\alpha_2 = \sqrt{3\alpha_1 + 5}$, and $L = \mathbb{Q}(\alpha_1, \alpha_2)$. The discriminant of $\mathbb{Z}[\alpha_1, \alpha_2]$ is $-2^{10}5^3$, $\text{rdisc}(\alpha_1, \alpha_2) = 2^{15}$, and the smallest integer defect is 2. Now $L$ also equals $\mathbb{Q}(\alpha_2)$. The discriminant of $\mathbb{Z}[\alpha_2]$ is $-2^{10}3^45^3$, $\text{rdisc}(\alpha_2) = 2^43^25$ and the smallest integer defect is 6. The discriminant of $\mathbb{Z}[\alpha_1]$ is 20, $\text{rdisc}(\alpha_1) = 10$ and the smallest integer defect is 2.

If the gcd of $f_1, f_2$ is a small expression, we would like to find it quickly. However, $1/\Delta \in L$ could be a large expression, especially when there are multiple extensions. So computing $\text{rdisc}$ need not be cheap; it is a computation we want to avoid. But if $\text{rdisc}$ (or some other integer defect) is not known, then for computing the gcd of $f_1, f_2$ from modular gcd’s, we must reconstruct rational numbers, not integers, from their modular images. It seems that our objective, to find the gcd quickly whenever it is small, forces us to use rational reconstruction.

The remark after lemma 9 gives a very fast way to test if $p$ divides the (reduced) discriminant. We found experimentally that this test has an insignificant impact on the total running time. However, according to theorem 1 it is sufficient to avoid lc-bad primes. So the discriminant-test can safely be omitted.

## 4 Implementation

In this section we describe our implementation of the modular GCD algorithm for multivariate polynomials over $L$. There are several multivariate “modular” GCD algorithms over $\mathbb{Q}$ that one may consider extending to work over $L$. We have completed an implementation of Brown’s algorithm (see [3]) which uses rational reconstruction and trial division (see [7]), and have begun work on an implementation of Zippel’s algorithm (see [10]).

We will first give details of the data structure we use for multivariate polynomials over $L$. The data structure is designed to make the modular GCD algorithm fast. It supports $n \geq 0$ extensions over $\mathbb{Q}$ and $\mathbb{F}_p$. We have encountered three bottlenecks on real problems, namely, (i) the trial divisions, (ii) rational reconstruction, and (iii) extensions of low degree. We will address (i) and (ii) in this paper. Problem (iii) is addressed in [7].
To fix notation, recall that \( L = \mathbb{Q}(\alpha_1, \ldots, \alpha_n) \) where \( \alpha_i \) is algebraic over \( L_{i-1} = \mathbb{Q}(\alpha_1, \ldots, \alpha_{i-1}) \), and \( m_i(z_i) \in L_{i-1}[z_i] \) is the minimal polynomial for \( \alpha_i \) over \( L_{i-1} \). Let \( R = L[x_1, \ldots, x_k] \). Let \( f_1, f_2 \) be non-zero polynomials in \( R \) and let \( g \) be their gcd.

As part of the preprocessing of the input polynomials, we compute \( \tilde{f}_1 \) and \( \tilde{f}_2 \), that is, we cancel any rational scalar before proceeding. We do not compute \( f_1 \) or \( f_2 \) which can cause a blowup. Let \( \text{ic}(f) \) denote the integer content of a polynomial. This is the rational constant \( c \) such that \( f/c = \tilde{f} \), the semi-associate of \( f \). For example, if \( f = 10/3x^2 - 15 \) then \( \text{ic}(f) = 5/3 \) and \( \tilde{f} = 2x^2 - 9 \).

### 4.1 A Data Structure for \( R \)

We have chosen the recursive dense representation for our polynomials. In [8], Stoutemyer asked the question “Which polynomial representation is best?” (for a general purpose computer algebra system). Based on his data, he concluded that the recursive dense representation was best overall, a conclusion that ran contrary to the general belief that one must use a sparse representation. In our context, where we are looking at the modular GCD algorithm over \( L \), we have additional reasons to choose this representation. Our input polynomials to the modular GCD algorithm are multivariate polynomials in \( x_1, \ldots, x_k \) and \( z_1, \ldots, z_n \). Because the modular GCD algorithm is recursive and because the extensions must also be defined recursively if they are dependent, a recursive data structure is a natural choice. Thus we think of the polynomials being in \( \mathbb{Q}[z_1][z_2][z_3][x_1][x_2][x_3] \). Moreover, because we compute the GCD modulo machine primes \( p_1, p_2, \ldots \), most of the real “work” takes place in the last variable, i.e. in the ring \( \mathbb{F}_p[z_1] \). For efficiency, we want to represent polynomials in \( \mathbb{F}_p[z_1] \) as dense vectors of machine integers. We now describe the data structure \(<\text{poly}>\) using a BNF notation with some examples.

\[
\begin{align*}
\text{<poly>} &::= \text{POLYNOMIAL( <ring>, <data> )} \\
\text{<ring>} &::= [ \text{<char>}, \text{<variable>}, \text{<exts> } ] \\
\text{<char>} &::= \text{<nonnegative integer>}
\end{align*}
\]

\[
\begin{align*}
\text{<data>} &::= \text{<rational number> | <immediate integer> } \\
&\quad\text{vector(<data>)}
\end{align*}
\]

\[
\begin{align*}
\text{<vars>} &::= \text{vector(<variables>)}
\text{<exts>} &::= \text{vector(<data>)}
\end{align*}
\]

The characteristic of the ring is encoded by \text{<char>} and \text{<exts>} is a vector of the minimal polynomials. Thus the ring for the polynomial is encoded
in the data structure. Since this information is identical for polynomials in
the same ring it should be stored once so that the cost of storing the ring
information is one word.

We impose the following important restriction which is the key idea of
the recursive dense representation; a zero coefficient at any level in the data
structure is represented by the immediate integer 0. This means that every
algorithm must treat 0 as a special case. This exceptional case does not
bother us greatly because in the implementation of most operations 0 is a
special case anyway.

The bottom of the data structure is a word of storage which is either
a pointer to a rational number or an immediate integer. In our Maple
implementation, immediate integers are signed integers of 30 bits in length,
and one bit is used to distinguish them from pointers.

In the examples below, vectors are indicated by square brackets.

**Example 1:** The representation of the polynomial $z^4 - 10z^2 + 1$ in char-
acteristic 0 and characteristic 3 is

POLYNOMIAL( [0,[z],[]], [1,0,-10,0,1] )

POLYNOMIAL( [3,[z],[]], [1,0,2,0,1] )

The empty vector [] indicates that there are no extensions and the data
in both these examples is a vector of machine integers. Allowing one word
as a header word for the POLYNOMIAL structure and for each vector, the
storage requirement for both polynomials is 16 words (count one word for
POLYNOMIAL and each | in the above). Since the ring information can be
shared between polynomials over the same ring, a more accurate count is
that 9 words are required. From now on we will not count the storage for
the ring.

**Example 2:** The representation of the polynomial $x^3 - zx + z^2$ in $\mathbb{Q}[z][x]$
and $\mathbb{Q}[z]/<z^2 - 2>$ is

POLYNOMIAL( [0,[x,z],[]], [[0,0,1],[0,-1],0,[1]] )

POLYNOMIAL( [0,[x,z],[[-2,0,1]]], [[2],[0,-1],0,[1]] )

In the data structure, polynomials are reduced modulo the $m_i$ on input.
The storage requirement is 17 and 15 words respectively.

**Example 3:** The recursive dense data structure is not sparse, but neither is
it truly dense. On sparse polynomials, the storage requirement is still very
good. The additional computation with zero coefficients is very low because
for arithmetic operations, adding, subtracting and multiplying 0 does not require any explicit work. Consider the sparse polynomial $2x^n + 3y^n + 4z^n + 5$ where $n = 3$. Our data structure for this polynomial is

$$\text{POLYNOMIAL}([R, [[[4, 0, 0, 3], 0, 0, [2]], 0, 0, [1]]])$$

This is 24 words (not counting the storage for the ring). In general it is $15 + 3n$ words. One of the main sparse representations for polynomials that is used in AXIOM is a linked list of pairs where each pair is a pointer to a coefficient and a pointer to a monomial where the monomial $x^iy^jz^k$ would be stored as an exponent vector $[i, j, k]$. Thus each non-zero term of the polynomial requires $2 + 2 + 4 = 8$ words of storage. On our example this would be 35 words, allowing 3 words for the top level of the data structure.

Of course, this is not truly a sparse data structure because the monomial representation is not sparse. Nevertheless, on this example, the recursive dense representation uses less storage for $n \leq 6$.

**Example 4:** Multiple extensions are handled in the obvious way. The polynomial $x + \sqrt{1/5} y + \sqrt{1 + \sqrt{1/5}}$ is represented by

$$\text{POLYNOMIAL}([0, [x, y, z1], [[[[-1, -1], 0, [1]], [-1, 0, 5]], [[[0, [1]], [[0, [1]], [[1]]]]])}$$

where the two minimal polynomials $m_1(z_1)$ and $m_2(z_2)$ have been replaced by $\bar{m}_1$ and $\bar{m}_2$. We remark that although this makes the test for whether a prime $p$ in the modular GCD algorithm divides $\text{den}(m_k)$ easy, and makes reduction of the minimal polynomials modulo $p$ easy, after having reduced the minimal polynomials modulo $p$, one should make them monic over $\mathbb{F}_p$ so that we do not repeatedly invert their leading coefficients.

We end with some remarks about the data structure.

- The data structure supports multivariate polynomials over $\mathbb{Q}$ and $\mathbb{F}_p$ with $n \geq 0$ simple algebraic extensions. Our implementation of the GCD algorithm also supports the finite field/ring case, i.e. multivariate polynomials over finite fields or rings with $n \geq 0$ extensions. The main difficulty there is how to deal with small finite fields.

- The representation of an element $a$ in $\mathbb{F}_p$ is $\text{POLYNOMIAL}([p, [0, 0]], a)$ which requires 3 words of storage (not counting the ring information). For example, the lc operation returns such an object. In the modular GCD algorithm, most of the time is spent working with vectors over $\mathbb{F}_p$ and $\mathbb{Q}$. Special code is included for the case of $\mathbb{F}_p$; it does not explicitly create constant polynomials.
4.2 Rational Reconstruction

If one naively applies rational reconstruction after computing the GCD modulo each prime \( p \), the cost of the rational reconstruction may become the bottleneck asymptotically as well as in practice. Suppose \( g = x + a \) and \( a \) is an integer of \( m \) digits in length. Then we need \( O(m) \) primes to reconstruct \( g \). The cost of Chinese remaindering will be \( O(m^2) \) but rational reconstruction will cost \( O(m^3) \). The reason is that Chinese remaindering can be done “incrementally” after each prime in \( O(m) \) time but, as far as we know, rational reconstruction cannot. We resolved this problem by attempting rational reconstruction after 1, 2, 3, 5, 8, 13, \ldots primes. This ensures that the asymptotic cost of rational reconstruction is no more than Chinese remaindering.

4.3 Trial Division

Another bottleneck of the modular GCD algorithm is the trial divisions. If \( h \) is the result of rational reconstruction then we must check that \( h|f_1 \) and \( h|f_2 \) to show that \( h = g \). Because these trial divisions can be expensive, we have considered abandoning trial divisions altogether in favor of a probabilistic result, that is, check that result of rational reconstruction agrees, say, with the GCD modulo five additional primes. However, in many applications where one computes GCDs, for example, normalizing a rational function, one wants to compute also the cofactors \( f_1/g \) and \( f_2/g \), hence, the divisions cannot be avoided.

For example, if Trager’s factorization algorithm is used to factor a polynomial \( f \in L[x] \) where \( k = \lbrack L : \mathbb{Q} \rbrack \), one computes \( g_1 = \text{GCD}(f, f_1) \) where \( f_1 \) is an irreducible polynomial over \( \mathbb{Q} \) and \( f_i \) is the norm of a factor of \( f \). Since the degree of \( g_1 \) is known to be \( d = \deg f_1/k \) in advance, it is not hard to see that if the modular GCD algorithm constructs a polynomial \( h \) of degree \( d \) and \( h|f \) then \( h \) must also divide \( f_1 \) and hence \( h = g_1 \). Since one also wants compute the cofactor \( f_1/g_1 \) in Trager’s algorithm, but not the cofactor \( f_1/g_1 \), then the latter trial division, which is usually the larger in degree, may be avoided. This simple observation can make a significant improvement.

We can use either classical division or a modular division algorithm. If \( g \) is small in size compared with \( f_1 \) and \( f_2 \) then classical division is asymptotically faster. On the other hand, if \( g \) is of similar size to its cofactors \( f_1/g \) and \( f_2/g \) then a modular division algorithm will be asymptotically faster. When dividing \( f_1 \) and \( f_2 \) by \( h \) over \( L \) using the classical division algorithm, a significant improvement (we saw a speedup of a factor of 10 on one large example) can be obtained if one avoids fractions as much as possible. Notice
that the leading coefficient of \( \hat{h} \) in the modular GCD algorithm is an integer. If also \( l_i = \text{den}(m_i) = 1 \), which is often the case, then the entire division algorithm can be completed using only integer arithmetic. If \( l_i \neq 1 \) for some \( i \) then the division algorithm can still be modified to avoid fractions.

We will describe how to do this for univariate polynomials with one field extension with minimal polynomial \( M \). We will call the algorithm \texttt{FFTDIV} (fraction-free trial division).

\textbf{Algorithm FFTDIV}

\textbf{Input}: \( A, B \in \mathbb{Q}[x, z], \ M \in \mathbb{Z}[z] : B \neq 0, \text{lcm} B \in \mathbb{Q}, \) and \( \deg M \geq 1 \).

\textbf{Output}: \( Q = A/B \mod M \) if \( B \mid A \mod M \); \texttt{FAIL} otherwise.

Set \( m = \deg_x A, \ n = \deg_x B \) and \( d = \deg_z M \).

Set \( i_a = \text{ic}(A) \) and \( a = A/i_a \).

Set \( i_b = \text{ic}(B) \) and \( b = B/i_b \).

Set \( l_b = \text{lcm} b \) and \( l_m = \text{lcm} M \).

Set \( s = 1, \ r = a, \) and \( q = 0 \).

While \( r \neq 0 \) and \( m \geq n \) do

Set \( l_r = \text{lcm}_x r \). Note that \( l_r \in \mathbb{Z}[z] \).

Set \( g = \text{GCD}(\text{ic}(l_r), l_b) \) and \( l_r = l_r/g \).

Set \( s = (l_b/g) \times s \).

Set \( t = l_r \times x^{m-n} \) and \( q = q + t/s \).

Set \( r = (l_b/g) \times r - t \times b \).

Set \( p = 1 \).

While \( r \neq 0 \) and \( \deg_x r \geq d \) do

Set \( l_r = \text{lcm}_x r \). Note that \( l_r \in \mathbb{Z}[x] \).

Set \( g = \text{GCD}(\text{ic}(l_r), l_m) \) and \( l_r = l_r/g \).

Set \( t = l_r \times x^{d - \deg_x r - m} \) and \( p = p \times (l_m/g) \).

Set \( r = (l_m/g) \times r - t \times M \).

Set \( s = s \times p \).

Set \( m = \deg_x r \).

If \( r \neq 0 \) then output \texttt{FAIL}.

Set \( Q = (i_a/i_b) \times q \) and output \( Q \).

The algorithm first makes the inputs \( A \) and \( B \) primitive over \( \mathbb{Z} \). We claim that each time round the outer loop \( r \) and \( q \) satisfy \( a = bq + cr \) for some scalar \( c \in \mathbb{Q} \) and \( r \) has integer coefficients. The outer loop reduces the degree of the remainder \( r \) in \( x \). In the outer loop we multiply \( r \) by the smallest
possible integer so that \( \text{lc}_x r \), a polynomial in \( \mathbb{Z}[z] \), will be divisible by \( \text{lc}_x b \). The inner loop then reduces the remainder \( r \) modulo \( M \). In the inner loop we multiply \( r \) by the smallest integer so that \( \text{lc}_x r \), a polynomial in \( \mathbb{Z}[x] \), will be divisible by \( \text{lc}_x M \). The integers \( s \) and \( p \) are multipliers. They keep track of the integer factors of \( \text{lc}_x b \) and \( \text{lc}_x M \), respectively, that \( r \) was multiplied by so that the quotient \( Q \) may be correctly computed from \( q \).
